Abstract

Can sentiment analysis be used in an educational context to help teachers and researchers evaluate student’s learning experiences? Are sentiment analyzing algorithms accurate enough to replace multiple human raters in educational research? A dataset of 333 students evaluating a learning experience was acquired with positive, negative, and neutral sentiments. Nine machine learning algorithms were used in five experimental configurations. Two non-learning algorithms were used in two experimental configurations. Each experiment compared the results of the algorithm’s classification of sentiment (positive, neutral, or negative) with the judgment of sentiment by three human raters. When excluding neutral sentiment, 98% accuracy was achieved using naive bayes. We demonstrate that current algorithms do not yet accurately classify neutral sentiments in an educational context. An algorithm using a word-sentiment association strategy can achieve 87% accuracy and did not require pretraining the model, which increases generalizability and applicability of the model. More educational datasets with sentiment are needed to improve sentiment analysis algorithms.

Keywords: sentiment analysis, educational research, machine learning, learner experience.

1. INTRODUCTION

Sentiment analysis is the identification of attitude, opinions, and emotions in a statement (Tang et al., 2015). Pang and Lee (2004) used sentiment analysis to classify opinions of movies in statements written online by movie watchers. Other uses of sentiment analysis have been to understand the opinions of customers regarding products, sentiment of airline travelers expressing their opinions online, and identifying positive and negative attitudes in tweets. Sentiment analysis has many subfields which solve personality recognition, sarcasm detection, metaphor understanding, aspect extraction, and polarity detection (Cambria et al., 2017). Sentiment analysis has been successfully used in marketing, product development, politics, etc.

Machine learning (ML) is one approach to sentiment analysis that involves a pretraining phase to learn from labeled data. Examples of ML algorithms include naïve bayes, support vector machines, logistic regressions, random forests, etc. Pang and Lee achieved 86% classification of sentiment accuracy in movie reviews with naïve bayes and support vector machine. Neural networks have been applied to sentiment analysis and resolve many of the lower-level NLP tasks, such as tokenization, part of speech recognition, etc. (Zhang et al., 2018).

In contrast to ML, rule-based models are expert systems that use a set of rules to achieve a conclusion or classification (Grosan & Abraham, 2011). Valence Aware Dictionary and Sentiment Reasoner (VADER) is a lexicon and rule-based sentiment analysis model used to detect sentiments in social media posts from word-
emotion associations. VADER is available in the Natural Language Toolkit package (NLTK; http://nltk.org). NRC Word-Emotion Association Lexicon (EmoLex) uses a list of English emotion lexicon labeled by eight basic emotions (anger, fear, anticipation, trust, surprise, sadness, joy, and disgust) and two sentiments, negative and positive (Saif, 2021). The labeling was originally performed by crowdsourcing.

Similar to the needs of organizations to understand the opinions of their patrons, educators need to understand the opinions and sentiments of their learners. Sentiment analysis may be able to help in an educational context.

2. LITERATURE REVIEW

Rani and Kumar (2017) propose using natural language processing and ML as a tool to help university administrators process student feedback. They used NCR Emotion Lexicon (EmoLex) to classify emotions and infer satisfaction and dissatisfaction by students in coursera.org courses. They observed that class performance (course grade) is highly correlated with student-course survey results.

Munezero et al. (2013) use sentiment analysis to extract emotions from learning diaries. Learning diaries are written reflections regarding students’ learning experiences. Munezero et al. propose using sentiment analysis to help the instructor identify emotions and track changes overtime, which can be a labor-intensive task without computational aid.

One research question is to investigate which sentiment algorithms provide the highest classification accuracies in an educational content. Do the sentiment algorithms achieve the same result as human raters? Can one be a substitute for the other?

One challenge is that sentiment analysis via machine learning requires large quantities of data (Cambria et al., 2017). Existing sentiment analysis algorithms have been trained from data in non-educational domains, often from numerous online product reviews, Twitter feeds, or political forums (Yue et al., 2019). Educational research does not have the large datasets to train machine learning. Different domain data means potentially different patterns and lexicons. As a research question, can existing algorithms trained in non-educational domains perform as well as or better than training a ML algorithm only on smaller educational datasets?

Transfer learning may help resolve these challenges. Transfer learning takes an algorithm designed in one domain on an unrelated, large dataset and applies it to another domain. The algorithm learns quickly to adapt as the researcher feeds new, smaller but domain-relevant data into the pretrained algorithm for model refinement (Yang et al., 2020; Zhuang et al., 2021). The pretrained algorithm may have been trained on millions of data points and the smaller dataset may only have a few hundred. The premise is that the pretrained algorithm may share many of the foundational NLP learning that still apply to the smaller dataset. The smaller dataset offers the algorithm specific context in which to learn new patterns.

3. METHODOLOGY

We propose that sentiment analysis be used to investigate the learner’s experience of a learning treatment. Instead of using multiple human raters to evaluate student’s opinion about the learning experience, a sentiment analysis algorithm could be used. Specifically, we investigate algorithms to identify the positive/negative sentiments in an experimental treatment on student learning in computer information system (CIS) courses.

Participants and Design

Graduate and undergraduate students in three CIS courses (8 sections) were taught and practiced time management as a professional development skill. Quantitative measures of grade performance were measured. The main finding regarding the learning of time management skills on grades is reported in Humpherys and Lazrig (2021). In that study, a survey was administered regarding students’ perceptions of the learning exercise with the question “Each week you were asked to preplan your study schedule and identify your deliverable. Did this activity help you improve your time management skills? Why or why not? You get points for participation, not for any predefined answer.” 180 student reviews were collected, includes judgement of sentiment (positive, negative, and neutral) from three human raters. This current study uses machine learning sentiment analysis to compare the performance of algorithms to the human raters.

Measures

Sentiment is the construct in question. Sentiment was derived by human raters and by algorithms then compared for accuracy as follows.
**Human rater-derived sentiment**—the sentiment assigned by three human raters regarding the participant's review of the experimental treatment. The human raters encoded as -1 for negative, 0 for neutral, and 1 for positive sentiment. The average of the human raters is calculated and rounded to the nearest integer. Positive indicates a sentiment of improvement in time management, positive results, or valuable learning experience. Neutral indicates the participant expressed no improvement in time management or was indifferent to the learning experience. Negative expresses a decrease in time management, negative results, or dissatisfaction with the learning experience.

**ML-derived sentiment**—encoded as -1 for negative, 0 for neutral, and 1 for positive sentiment derived from a machine learning, sentiment analyzing algorithm. Various algorithms are used and explained later.

**Accuracy**—how well the ML algorithm predicted the same sentiment score (positive, neutral, negative) as the human raters. The human rater-derived sentiment was considered ground-truth. Accuracy is a percentage representing the number of sentiments correctly classified by the algorithm divided by the total number of sentiments (Hossin & Sulainman, 2015).

\[
\text{accuracy} = \frac{TP + TN + TN_u}{TP + TN + TN_u + FP + FN + FN_u}
\]

Table 1 shows the definition of terms used when calculating accuracy. Each term is a count (integer). For example, if the algorithm classified a student’s comment as negative sentiment but the human rater-derived sentiment was either positive or neutral for the same student's comment, the count of false negatives was incremented. This process was repeated for every data point in the datasets.

**Learning Sentiment dataset**—The dataset has a total of 333 student reviews. 180 students reviewed a time management learning exercise in three CIS courses of which 154 are positive. To increase the number of negative and neutral sentiments, 153 student reviews regarding instructors and courses were collected from rateMyProfessor.com. RateMyProfessor.com lets students write evaluations about courses and comments. In addition to the text-based comments, students select a quality score of 1-5. Quality scores of 4 or 5 is labeled “awesome,” 3 is considered “average,” and 2 or 1 is considered “awful.” Furthermore, green, yellow, and red icons are associated with the respective quality scores/labels, which can be equated to positive, neutral, or negative sentiment respectively.

First, the ratings were filtered for “West Texas A&M University” to match the original data's student population. Next, a random course was selected, but not the same as the 3 CIS courses in the original 180 student review. “Awesome”
quality scores were ignored, given the desire to collect more neutral and negatives comments. If the quality score was a 1, 2, or 3, a human rater read the student’s comment. If the human rater agreed that the student’s comment is classifiable as a quality score 1, 2, or 3, the comment and quality score were included in the Learning Sentiment dataset. The quality score was recoded to match the sentiment score in the original dataset. A 1 or 2 quality score was recoded as negative sentiment (i.e., a -1 value in the Learning Sentiment dataset). If the quality score was 3, the sentiment was recoded as neutral (0 value).

These extra reviews were collected to balance more closely the positive and negative reviews and increase the neutral reviews in the dataset. The limitation of the extra review data is that the learning experienced by the students was not just about the time management exercise, as originally planned. But since the research questions are about the accuracy of the sentiment algorithms, not about the learning exercise, this limitation should not impact the validity of the sentiment accuracy results. In addition, the threat to validity of an unbalance dataset where the ML algorithm learns to predict all data as positive sentiments is a greater threat than the limitation of adding extra reviews from different courses. The final sentiment counts in the Learning Sentiment dataset are 154 positive, 48 neutral, and 131 negative.

**Learning Sentiment without Neutral dataset**—Neutral sentiments were removed from the Learning Sentiment dataset because neutral sentiments have demonstrated difficulty to evaluate in past research and to compare with publicly available datasets that do not include neutral sentiment. This results in 154 positive and 131 negative data points. The accuracy calculation therefore removes TNu and Fnu as terms.

**Movie Review dataset**—The movie reviews dataset is included in the Natural Language Toolkit corpus package (http://nltk.org). The dataset was originally collected by Pang and Lee (2004) and has 2,000 reviews with 50% negative sentiment, 50% positive, and no neutral. The movie reviews were written before 2002 on www.rottentomatoes.com by 312 authors with a maximum of 20 reviews per author.

**Airline Review dataset**—The airlines dataset contains 14,640 tweets of a US Airline in February 2015 with 2,363 classified as positive, 9,178 classified as negative and 3,099 as neutral (Crowdflower, 2019).

**Airline Review without Neutral dataset**—Neutral sentiments were removed from the Airline Review dataset to pretrain some ML models for transfer learning.

**Data preprocessing**
The preprocessing stage prepares the five datasets for sentiment analysis by cleaning and vectorizing the data. Cleaning the data: removing irrelevant terms, names and symbols and converting all words into lower case to simplify word matching procedure. In addition, some high frequency words are filtered out as stopwords. Vectorization: converting the cleaned text into numerical vectors to be used as features in the algorithm. A tokenizer split the text into words, or tokens (known as bag of words), then converts them into a feature vector based on word count or term frequency-inverse document frequency (TF-IDF), which is a statistical measure that evaluates how relevant a word is to a document in a collection of documents.

**Experimental Configurations**
To answer the research questions, we ran seven sets of experiments. In experiments 1-5, we used the Natural Language Toolkit (https://www.nltk.org) for natural language processing and we used the scikit-learn library in Python (https://scikit-learn.org/) for the machine learning algorithms. Local-training means we used the Learning Sentiment data for training and testing the algorithms. Local-training gives a baseline to compare against transfer learning using external-training models. External-training means the ML models are pretrained (transfer learning) using the airlines dataset or movie reviews dataset. Then, the model is tested for accuracy with the entire Learning Sentiment data. It is anticipated that external-training can overcome the relatively small sample size of the Learning Sentiment dataset and simulate the desired outcome of being able to replace human raters in educational research.

Experiment #1 uses the Learning Sentiment dataset for both training and testing. Nine classification algorithms were used (see Appendix A). We employed a 10-fold cross-validation method to calculate the average accuracy. In each fold, the dataset is randomly shuffled and divided into training and testing subsets with the ratio 80:20, then the 10 accuracies are averaged. This process is repeated for each of the nine classification algorithms. Cross-fold validation reduces overfitting and increases generalizability.
Experiment #2 uses the Learning Sentiment without Neutral dataset and repeated the procedures of Experiment #1. Since most of the false positives and false negatives in Experiment #1 were due to the misclassification of the neutral sentiments, we decided to investigate the accuracies without neutral reviews. Even human raters can display lower inter-rater consistency when classifying neutral sentiments.

Experiment #3 uses the Movie Review dataset to pretrain the ML model. All 285 records in the Learning Sentiment without Neutral dataset are used for testing the accuracy of the ML model, since the Movie Review dataset does not have neutral sentiments.

Experiment #4 uses the Airlines Review dataset for pretraining the ML model. All 333 records in the Learning Sentiment dataset are used for testing accuracy because the Airlines Review dataset does include neutral sentiments.

Experiment #5 uses the Airline Review without Neutral dataset for pretraining the ML model. All 285 records in the Learning Sentiment without Neutral dataset are used for testing the accuracy of the ML model. This allows for comparison to Experiment #3 regarding transfer learning.

We included two more experiments (Exp#6 and Exp#7) that use rule-based modeling rather than ML, namely VADER and EmoLex. VADER returns a composite real score value between -1 and 1 for the sentiment of a given text with -1 for most negative, +1 for most positive, and around zero for neutral. We set a threshold for the neutral sentiments to be between -0.05 to +0.05. The EmoLex algorithm returns integer scores for positive and negative words in the text. We compare the two scores to determine the overall sentiment of the text. If the positive score is greater than the negative, then the final sentiment will be positive and vice versa. If both are similar or both are zero, the sentiment will be neutral.

Experiment #6 uses the rule-based VADER and EmoLex models to test the accuracy of sentiment detection on the Learning Sentiment dataset.

Experiment #7 uses the rule-based VADER and EmoLex models to test the accuracy of sentiment detection on the Learning Sentiment without Neutral dataset.

4. RESULTS

Table 3 summarizes the highest accuracies of sentiment classification achieved in each experiment #1-7 and the algorithm that performed the best.

Note. * Experiments #6 and #7 use rule-based modeling: VADER and EmoLex.

The highest accuracies in experiments #1-5 are as follows: The naive bayes, random forest, and logistic regression ML algorithms had accuracies of 85% in Experiment #1 and up to 98% when neutral sentiments were removed in Experiment #2. Pretraining the ML model from movie reviews and validating the accuracy on the Learning Sentiment without Neutral dataset (Experiment #3) saw classification accuracies up to 77%. Pretraining the ML model using the Airlines database (with and without neutrals) performed worse. External training did not improve classification algorithms over the local training. Appendix A shows the accuracy results of experiments #1-5 for the nine ML algorithms considered.
Experiments #6 and #7 use rule-based modeling, specifically VADER and EmoLex. VADER achieved accuracy of 72.3% in experiment #6 and 86.7% in experiment #7. EmoLex achieved 55.0% in experiment #6 and 73.8% in experiment #7. Experiment #6 used the full Learning Sentiment dataset. Experiment #7 used the Learning Sentiment dataset with neutral sentiments removed.

5. DISCUSSION

This study proposes using sentiment analyzing algorithms to evaluate sentiment in an educational context. Teachers could use sentiment analysis to quickly evaluate sentiment from student reviews after administering a learning exercise or from course evaluations. Researchers could save time and resources when evaluating an educational treatment for sentiment by replacing multiple human raters with a sentiment analyzing algorithm. Sentiment can be positive, negative, or neutral. Sentiment analysis has largely been used in product/service reviews, movie reviews, and politics. Can sentiment analysis perform accurately in an educational context?

The experimental configuration with the highest sentiment accuracy was Experiment #2, which used the Learning Sentiment without Neutral dataset for both training and testing. Accuracy of predicting positive and negative sentiment reached 98% using naive bayes. For predicting positive, negative, and neutral, the highest performing algorithms were in Experiment #1, which used the Learning Sentiment dataset for both training and testing. In this configuration, naive bayes, random forest, and logistic regression produced accuracies of 85%. These results show the potential of using sentiment analysis in education.

From these results we deduce that neutral sentiment is hard to detect. The observed lower accuracies in some experimental configurations was due to misclassification of the neutral sentiments. Our recommendation is that if a teacher or researcher wishes to apply sentiment analysis to an educational context, they are currently limited to only positive and negative sentiment, not neutral, at least until the neutral-detecting algorithms improve.

Another research question is whether or not sentiment analyzing algorithms perform accurately enough to replace human raters. The scenario is a researcher evaluating an educational treatment regarding the sentiment of the learner.

The Learner Sentiment dataset originally used three human raters to assess sentiment. Can an algorithm be used to replace the human raters? The requirement for success of this proposal is that the researcher should not use the target dataset to train the ML model, as in Experiments #1 and #2, because it would defeat the purpose of performing a sentiment analysis on unlabeled data and without human involvement. Experiments #3 through #7 tested this scenario. Experiments #3, #4, and #5 used ML models pretrained from movie reviews and airline reviews. Pretraining with those dataset offered tens of thousands of records to refine a sentiment model before applying the model to a target educational dataset. However, accuracy rates only rose to 77%. The sentiment models trained on the movie reviews and tested on the Learning Sentiment without Neutral dataset (Experiment #3) performed better than the models trained on the airline reviews dataset (Experiment #4 and #5).

We conclude that the movie review data is closer in characteristics to the educational dataset than the airline reviews dataset. The pretrained models became domain-dependent. The airlines dataset entries are short tweets while the movie reviews dataset entries were longer reviews. The vocabulary distribution across the opinions is different between the two datasets. Neither dataset is sufficient to offer a viable replacement to human raters. Data domain is very important for supervised ML sentiment analysis. Because sentiment domain-specific datasets are sparse in educational research, we opine that if ML algorithms are to be improved more educational datasets need to be collected and publicly available, following ethical guidelines for privacy. When a model was trained on educational data the ML algorithms perform as well as human raters at identifying positive and negative sentiment with the advantage of speed and automation.

Unsupervised algorithms, like VADER, are promising. In Experiments #6 and #7, pretraining the sentiment model was not required. One could take the VADER rule-based algorithm as is and evaluate a target dataset for sentiment. The VADER algorithm performed better than many of the supervised ML algorithms with 72% accuracy for the Learning Sentiment dataset with neutral sentiments included and 87% when the neutral sentiments were removed. Arguably, 87% is approaching accurate enough to be useful in an educational context. The VADER algorithm is useful for getting a quick and general (summarized) view or trend of students’ opinions.
about a topic without requiring human intervention, which could save resources and the instructor’s time. One application of using VADER in the classroom is to have students text opinions about a lecture topic, e.g. business case, scenario, or argument position, and the VADER algorithm can instantly quantify how many students expressed a positive or negative opinion about the business case. The summary can be presented back to the students as part of the same lecture. Sentiment analysis could be applied to short-essay assignments or to analyze exam responses. Another application can be for administrators to identify struggling teachers and offer assistance after using an automated sentiment analysis with course reviews. With thousands of students’ comments, reading all the comments may be fatiguing and ineffective, but an algorithm can identify positive and negative comments to focus an administrator’s caring attention.

In conclusion, the highest accuracies came from domain-specific training of ML algorithms. Rule-based word-sentiment association algorithms show promise as their accuracies approach those of ML. Future research is needed to accurately identify neutral sentiments. The end goal is for teachers and researchers to have an accurate tool to quickly evaluate the sentiment of a student's learning experience.
